Abstract

*Scolytoplatypodini* Blandford is a monotypic tribe of ambrosia beetles found in Asia, Madagascar and Africa. Only three species are currently known from Madagascar and four additional species are here described as new to science. Phylogenetic analyses of morphological and molecular data revealed that four of the seven endemic species are deeply separated from all other species by genetic and distinct morphological characters and therefore placed in a new genus *Remansus* Jordal. The split between this ancient lineage and *Scolytoplatypus* Schaufuss was estimated to approximate Palaeocene age (63 Ma), extending the minimum age of ambrosia feeding for this tribe to the beginning of the Palaeocene–Eocene thermal maximum (PETM). In addition to the ancient origin of *Remansus* in Madagascar during the Palaeocene, a second origin occurred in *Scolytoplatypus* no more than 13 Ma. A geographical origin of the latter in South-Eastern Africa was unequivocally inferred from the phylogenies.

Keywords

Curculionidae, Scolytinae, *Scolytoplatypodini*, molecular phylogeny, biogeography, Madagascar, PETM
Introduction

Madagascar has one of the highest diversity of plants and animals, a diversity reflected not only by the great number of plant and animal species, but also by a huge number of endemic lineages of higher taxonomic ranks. Forest insects are no exception to this pattern. Woodboring weevils in the subfamily Scolytinae and Platypodinae have dozens of genera and hundreds of species endemic to Madagascar, with several cosmopolitan genera forming particular voluminous species group radiations on this island (Schedl 1977).

*Scolytoplatypus* is currently the only recognised genus in the tribe Scolytoplatypodini, known from Asia, Madagascar and Africa (Beaver and Gebhardt 2006; Browne 1971; Schedl 1975). These medium to large sized beetles cultivate fungi used as food for their larvae, where females carry spores in a characteristic large dorsal mycangium situated in the anterior third of the pronotum (Figs 1 and 2). Males and females are strongly dimorphic, with the male frons distinctly concave as opposed to the convex female frons. Male protibiae are asymmetric and smooth on its posterior side, with two or more long lateral spines (Fig. 3), whereas the females have much broader protibiae with coarse granules on its posterior face. Browne (1971), and later Beaver and Gebhardt (2006), noted that the Asian species are distinct from the African and Malagasy species by having sexually dimorphic antennae, constricted lateral sides of pronotum in both sexes, and by the acute projections or nodules on the male prosternum. The affiliation of the Malagasy species has not yet been evaluated but no one has so far disputed a close relationship to the African species (see Schedl 1975).

In Madagascar the genus has relatively low diversity with only three species reported, compared to a total of 12 species in Africa (Schedl 1975) and 28 in Asia (Beaver and Gebhardt 2006). Recent field work on the island has revealed four undescribed species collected in very low numbers compared to the other known species in this area. Three of the new species possess morphological features shared with *S. mutabilis* Schedl that deviate from the typical *Scolytoplatypus* species, having a large, flat scutellum that is flush with the elytra, rounded postero-lateral angles of the pronotum (Fig. 7), and nearly parallel-sided male protibiae (Figs 4 and 5). These features are plesiomorphic and indicate a transition from a more typical scolytine bauplan. It is therefore possible that such distinct difference in morphology is reflected in molecular data and that a phylogenetic analysis will enable test of taxon distinctness.

This paper presents a revision of the Malagasy species of Scolytoplatypodini and attempts to relate these species to the African and Asian members of the genus. A phylogenetic analysis of morphological and molecular data is presented to assess the number of independent clades that occur in Madagascar and to document the existence of a new genus *Remansus* for the most ancient clade of Malagasy species. Molecular data are used to place the Malagasy species in an evolutionary time frame, and to explore the geographical origin of the scoliyooplatypodine fauna in Madagascar.
Materials and methods

Material of Malagasy Scolytoplatypodini was available from California Academy of Science’s biodiversity inventory 2000–2002 and from the author’s field collecting in 2012. Additional material collected by the author was available from Africa and Asia (Table 1). The following acronyms are used for the material studied: CAS, California Academy of Science; ZMBN, University Museum in Bergen; NHMW, Naturhistorisches Museum Wien.

Sequences were generated from the mitochondrial cytochrome oxidase 1 (COI) gene (690 bp) and the three nuclear genes CAD (490 bp), EF1α (857 bp) and 28S (865 aligned sites). DNA was extracted and amplified using the protocols and primers listed in Jordal et al. 2011. Phylogenies were estimated from a concatenated matrix of all four genes (2894 aligned sites) using the Bayesian criterion in the software MrBayes v. 3.2 (Ronquist and Huelsenbeck 2003), applying a GTR+I+G model. These data were also analysed by maximum parsimony using PAUP (Swofford 2002), with 200 heuristic searches, TBR and random addition of taxa. Bootstrap support was estimated from 200 replicates of 100 random additions for each replicate. The molecular phylogenies were compared to one based on parsimony analysis of 21 morphological characters (Table 2). The morphological analysis included one additional species for which molecular data were not available (R. serratus Jordal).

Table 2. Morphological characters used in the phylogenetic analysis.

1. Male frons convex (0); concave (1)
2. Male antennal club similar to female (0); prolonged (1)
3. Female pronotum with central mycangium absent (0); present (1)
4. Female mycangium placed about one quarter from anterior margin (0); one third or more from anterior margin (1); n/a (-)
5. Males with lateral fovea on pronotum absent (0); present (1)
6. Postero-lateral margin of pronotum straight in both sexes (0); constricted in females only (1); constricted in both male and female (2)
7. Posterior corner of pronotum rounded (0); with spine (1)
8. Posterior margin of pronotum straight (0); acuminate (1)
9. Scutellum is flush with elytra (0); or sunken and near invisible (1)
10. Striae on posterior half of the elytral disk of the male not impressed (0); strongly and broadly impressed (1)
11. Male declivity with interstriae 1, 3 and 5 on male declivity flat (0); convex (1); carinate (2)
12. Female declivity with all striae similarly impressed (0); not impressed or evident (1)
13. Base of declivity smooth (0); with a carinate ring or serration (1)
14. Female apex of the elytra rounded (0); extended into a flange (1)
15. Vestiture scattered and restricted to interstriae (0); uniformly pilose (1)
16. Females with a patch of longer setae close to the elytral apex absent (0); present (1)
17. Procoxae contiguous (0); separated (1)
18. Female protibiae: narrow, parallel-sided and smooth (0); broad, with coarse spines (1)
19. Male protibiae nearly parallel-sided (0); strongly curved and asymmetric (1)
20. Prosternum in males simple, smooth (0); or extended anteriorly into nodules or projections (1)
21. Dorsal side of profemur smooth (0); with spine (1)
The timing of Malagasy origins was estimated in the software Beast (Drummond and Rambaut 2007). Two different analyses were made. In analysis A, a minimum age of 116 Ma was set for the ingroup, defined as Scolytoplatypodini, *Scolytodes acuminatus* Wood and the Molytinae *Porthetes hispidus* (Boheman). In analysis B, a recently published estimate of 36 Ma was used for the most recent common node for three species of *Scolytoplatypus* (see Jordal and Cognato 2012), without constraining these monophyletically. Calibration of nodes was based on a normal distribution with a relatively broad standard deviation of 5 my.

**Results and discussion**

**Taxonomy**

*Scolytoplatypodini Blandford*

http://species-id.net/wiki/Scolytoplatypodini

**Revised diagnosis. Female.** *Frons* flattened to convex; antennal club flat, pilose, without sutures; *pronotum* with a dorsal mycangium (except seven species), pronotum weakly to strongly constricted laterally in posterior third, hind corners rounded or acute, posterior margin straight to strongly bisinuate; *scutellum* visible, narrow and sunken or broader and flush with elytra; *procoxae* widely separated; *protibiae* broad, on its posterior side with coarse granules and blunt spines, some forming rugae.

**Male.** Similar to female except *frons* slightly to very strongly concave, *pronotum* without mycangium, some with anterior fovea on lateral sides (Asian species), laterally constricted or not in posterior third; protibiae generally smooth on posterior side, sides straight to strongly curved and asymmetrical, laterally with small or large lateral spines.

**Included genera.** *Scolytoplatypus* Schaufuss and *Remansus* Jordal, gen. n.

**Distribution.** Asia, Africa and Madagascar.

*Scolytoplatypus Schaufuss, 1891*

http://species-id.net/wiki/Scolytoplatypus

**Type species.** *Scolytoplatypus permirus* Schaufuss.

For a complete diagnosis of the genus and discussions on morphological features, see reviews by Beaver and Gebhardt (2006) and Browne (1971).

**Malagasy species of Scolytoplatypus**

The genus in Madagascar includes three possibly monophyletic species whose ancestor colonized Madagascar rather recently. They have all typical features of the African lineage, including a sharp lateral spine at posterior corners of the pronotum, the female
mycangium about one-third or more from the anterior margin, a strongly bisinuate (acuminate) posterior margin of the pronotum, a narrow and sunken scutellum, and strongly asymmetrical male protibiae with a long and curved lateral distal spine. They lack a dorsal spine on the profemur and therefore key out in couplet 7 in Browne's (1971) key to African species, near S. fasciatus Hagedorn.

_Scolytoplatypus permirus_ Schaufuss, 1891

http://species-id.net/wiki/Scolytoplatypus_permirus

Figs 8–13

_Scolytoplatypus permirus_ Schaufuss, 1891: 31.

**Diagnosis.** Length 2.5–3.1 mm.

**Male.** Frons concave, marked at its upper margin by a small heart-shaped tubercle. Pronotum with a short spine in postero-lateral corners, posterior margin strongly bisinuate. Scutellum narrow, sunken between elytra. Elytral disk on posterior third and declivity with carinate interstriae and deeply excavated striae; interstriae 2, 4 and 6 not carinate on declivity; declivity in lateral profile gradually rounded.

**Female.** Similar to male except frons convex, pronotum with one large mycangial pore, posterior third of pronotum laterally constricted, posterior part of elytral disk smooth, declivity with shallowly impressed striae, interstriae 1, 3 and 5 weakly elevated, elytral apex broadly rounded, extended flange less transverse, with broad v-shaped emargination at suture; protibiae broad, posterior face tuberculate.

**Variability.** The amount of interstrial setae and granules on declivity varies considerably between individuals.

**Molecular data.** DNA barcodes in Table 1.

Deep phylogenetic divergence between *Scolytopterus* and *Remansus*...

A fairly common species throughout the wet forests of Madagascar, where it frequently co-occurs with *S. hova* Schaufuss. It breeds in small diameter branches, typically ranging between 2–5 cm. Previously known from Montagne d’Ambre and Joffreville in the north of the island, from Antananarivo, and in the east from Perinet in

**Figures 8–13.** *Scolytopterus permirus* Schaufuss. **8** male lateral view **9** male frons **10** male dorsal view **11** male declivity **12** female dorsal view **13** female declivity.
Andasibe national park (Schedl 1977). The many new records from the South-Eastern rain forest in Ranomafana documents its likely presence throughout the moist and wet forests of the island. This is a very polyphagous species, reported previously from 20 host plant species in 14 different plant families (Schedl 1977), adding here another three host genera and one new plant family (Annonaceae).

*Scolytoplatypus hova* Schaufuss, 1905

http://species-id.net/wiki/Scolytoplatypus_hova

Figs 14–19

*Scolytoplatypus hova* Schaufuss, 1905: 12.

**Diagnosis.** Length 3.5–4.5 mm.

**Male.** *Frons* concave, marked at its upper margin by a small protruding tubercle. *Pronotum* with a short spine in each postero-lateral corner, posterior margin strongly bisinuate. *Scutellum* narrow, sunken. Posterior half of elytral disk with carinate interstriae and deeply excavated striae; interstriae 2 closer to 3 than to 1 on disk, interstriae 2, 4 and 6 not carinate on declivity; transition from the smooth disk to posterior area with impressed striae angular, appearing hunchbacked, declivity in lateral profile angular.

**Female.** Similar to male except *frons* convex, *pronotum* with one large mycangial pore, posterior third of pronotum laterally constricted, striae not impressed, interstriae 1, 3 and 5 on declivity weakly elevated, declivity in lateral profile rounded, *elytral apex* transverse and extended between interstriae 1 and 3, with a narrow v-shaped emargination at suture.

**Molecular data.** DNA barcodes in Table 1.

**Distribution and biology.** New records: Antsiranana Prov, 7 km N Joffreville, 12°20'00"S, 049°15'00"E, MA-01-07-12, 13-16 May 2001, Malaise trap; Parc National Montagne d’Ambre [Petit Lac road], 12°31’13”S, 049°10’45”E, MA-01-01D-03, 29 Jan-11 Feb 2001, Malaise trap; Fianarantsoa Prov, Forêt d’Atsirakambiaty, 7.6 km 285° WNW Itremo, 20°35’36”S, 046°33’48”E, BLF7155, 22-26 Jan 2003, EB09 sifted litter (leaf mold, rotten wood); Fianarantsoa Prov, Ranomafana National Park, JIRAMA water works, 21°14’55”S, 047°27’08”E, MA-02-09D-08, 21-24 Dec 2001, malaise trap [CAS]. Fianarantsoa prov, Ranomafana NP, Vato trail [-21.29, 47.42], alt. 1100m, ex *Xylopia* branch, 2012: 4x-11, B.Jordal leg; Valo area [-21.31, 47.43], alt. 1100m, ex *Albizia* branch, 2012: 6x-9, B.Jordal leg. [ZMBN].

The biology and distribution of this species is similar to *S. permirus* and these two species frequently occur on the same host plant. Previously reported from the Montagne d’Ambre area in the North, from Moramanga and Perinet (Andasibe in Toamasina) east of Antananarivo, from Infanadiana (Fianarantsoa) in the south-east, and Fort Dauphin in the south (Schedl 1977). It has been collected from more than ten different host plant genera in eight plant families, adding another two families here (Fabaceae, Annonaceae).
Deep phylogenetic divergence between Scolytoplatypus and Remansus...

*Scolytoplatypus rugosus* Jordal, sp. n.
http://species-id.net/wiki/Scolytoplatypus_rugosus
Figs 20–25

Type material. Holotype, male: “Madagascar: Fianarantsoa, Ranomafana, Centre Val-Bio [-21.25, 47.42], alt. 950m, ex Harungana madagascariensis, 2012: 29ix-13, B."

Diagnosis. Male. Protibiae strongly curved and asymmetrical, scutellum narrowly triangular and sunken between elytra, pronotum with a lateral spine in each posterior corner.

Female. With mycangial pore on pronotum; declivity identical to male; frons and protibiae typical dimorphic as for the genus.

This species is closely related to S. fasciatus in south-eastern parts of Africa, but differs from that species by the lack of interstrial granules on declivity, by the more deeply impressed male frons, and by the uniform dark mature body colour. It differs further from all other African and Malagasy species by the transverse crest along the upper margin of the male frons. It is readily distinguished from males of the closely related Malagasy species S. hova and S. permirus by the much less impressed striae on posterior third of the elytral disk. From the African species S. opacicollis Eggers, S. obtectus Schedl and S. fasciatus, it is distinguished by the extended flange of the female elytral apex, and the stouter body plan (1.7–1.8 versus 2.0–2.1 times longer than wide).

Molecular data. DNA barcodes in Table 1.

Description. Male. Length 2.3-2.7 mm, 1.7–1.8× longer than wide; colour dark reddish brown to black.

Head. Eyes separated above by 4.2x their width. Frons concave from vertex to epistoma between inner eye margins, marked above by a distinct transverse crest at median third; impressed area weakly reticulated, with small shallow punctures separated by 1–2x their diameter, except smooth and shiny on a median triangular area on lower third. Vestiture consisting of short fine setae along the upper rim of concave area, and minute setae in punctures in concave area.

Pronotum 0.75x as long as wide, sides subparallel, surface finely reticulated with shallow punctures spaced by 1–2x their diameter; pronotal vestiture consisting of fine short setae arising from punctures, a few longer setae scattered close to anterior margin.

Elytra 1.0–1.1× longer than wide, 1.5–1.6× longer than pronotum; sides almost straight, broadly rounded behind, with an extended apical flange between suture and interstriae 5; striae impressed only on declivity, strial and interstrial punctures on disk confused, spaced by 1–1.5× their diameter; interstriae on declivity slightly raised, shrivelled, punctures asymmetric and confluent, surface strongly reticulate, mesh-like. Interstriae 10 weakly elevated to level of ventrite I. Vestiture consisting of minute setae in punctures only slightly longer than diameter of a puncture.

Legs. Procoxae separated by 0.6x the width of one coxa. Mesocoxae separated by 0.7x the width of one procoxae. Protibiae strongly asymmetrical, with one large laterally curved distal spine, one medium lateral spine and some 6–7 additional lateral small spiny granules.
Deep phylogenetic divergence between Scolytoplatypus and Remansus...

Ventral vestiture. Metanepisternum with short, bifid setae.

Female. Similar to male in most respect, including the declivity, but differ by the convex frons and more widely separated eyes (4.5× their width), pronotum laterally

constricted on posterior third, with mycangial pore on anterior third (0.35), by the broad protibiae with spines and granules on its posterior face, and by the broader pro-ternum being 0.8 as wide as one procoxa.

**Etymology.** The Latin masculine adjective *rugosus* means ‘wrinkled’ or ‘shrivelled’, referring to the surface of declivity with wrinkled interstriae, confluent asymmetrical punctures and strongly reticulate cuticle.

**Distribution and biology.** Only known from the southern range of the Ranomafana National Park. The collections from *Harungana* (Hypericaceae) and *Ocotea* (Lauraceae) indicate a broad host plant range typical for the genus. Branches between 2–5 cm in diameter were colonized, where male and female joined in monogamous pairs, with the male guarding the entrance when the female excavated the egg tunnels.

*Remansus* Jordal, gen. n.
http://zoobank.org/6C22EF3E-767C-42A5-A52F-CDAB20678DF8
http://species-id.net/wiki/Remansus

**Type species.** *Scolytoplatypus mutabilis* Schedl. Gender masculine.

**Diagnosis. Male.** *Frons* concave, antennal funicle 6-segmented, club flattened and pilose without sutures; *procoxae* widely separated, *protibiae* narrow, nearly parallel-sided; *pronotum* not constricted laterally, posterior corners rounded, posterior margin nearly straight; *scutellum* large, flush with elytra.

**Female.** Similar to male except *frons* flat to slightly convex; *pronotum* with a median mycangium about one-quarter distance from the anterior margin, posterior lateral margins of pronotum weakly constricted; protibiae very stout, broad, with coarse granules and rugae on its posterior side.

**Etymology.** Based on the Latin masculine participle meaning ‘left behind’ or ‘having endured’, referring to the first branch of Scolytoplatypodini that has remained in Madagascar since the origin of the tribe.

*Remansus mutabilis* (Schedl, 1965), comb. n.
http://species-id.net/wiki/Remansus_mutabilis
Figs 26–31

*Scolytoplatypus mutabilis* Schedl, 1965: 78.

**Type material examined.** Holotype, male: Madagascar, Perinet, 16.XI. 1952, K.E. Schedl, leg (NHMW).

**Diagnosis.** Length 3.0–3.4 mm.

**Male.** *Frons* weakly concave, with a feeble longitudinal carina from epistoma to vertex. *Elytra* smooth, striae not impressed on disc and declivity, vestiture of dense,
short, fine setae not in rows. Protibiae almost parallel-sided, with a moderately sized, curved lateral spine at distal end, and four additional smaller spines (granules) towards base. Procoxae rounded, separated by 0.7× the width of one coxa.
**Female.** Similar to male except frons weakly convex, eyes more widely separated; declivity near apex with two patches of longer and more densely placed setae; protibiae broad, with granules on posterior side. Procoxae very broad, separated by 0.8× the width of one coxa.

The female is here reported and diagnosed for the first time. It differs externally from the male only in those dimorphic features given in the diagnosis. This is the only species in *Remansus* with both male and female known.

**Molecular data.** DNA barcodes in Table 1.

Previously reported from Anjanaharibe and Marojejy forest reserves in the Northern part of the island, and in Perinet east of Antananarivo (Schedl 1977). The new collections from the Fianarantsoa district indicate a broad distribution across the forested parts of the country, although it seems less frequently collected, and in fewer numbers, compared to *S. hova* and *S. permirus*. The collection from *Albizia* (Fabaceae) is the first documented host plant for this species, but a much broader range of host plants is expected due to the association with ambrosia fungi.

*Remansus sahondrae* Jordal, sp. n.

http://zoobank.org/BAA6B09A-B9A3-4664-8A5A-7980711414DA
http://species-id.net/wiki/Remansus_sahondrae
Figs 32–35

**Type material.** Holotype, female: “Madagascar: Fianarantsoa, Ranomafana, Vato trail [-21.29, 47.42] alt. 1100m ex *Eugenia* branch. 2012: 2x-9, Sahondra Rahanitriniaina” / “ZMBN/ENT-Scol-8” Paratype, female: same data as holotype Rahanitriniaina label “ZMBN/ENT-Scol-9”. The holotype and paratype are deposited in the University Museum of Bergen (ZMBN).

**Diagnosis.** Female. Pronotum with mycangium only one-quarter distance from anterior margin, posterior corners rounded, posterior margin straight; scutellum flat at the same level as elytra. It is closely related to *S. mutabilis*, but distinguished from that species by the visible striae, larger elytral punctures, the coarse, short setae on the declivity, and by the much smaller body size.

**Molecular data.** DNA barcodes in Table 1.

**Description.** Female. Length 2.2–2.3 mm, 1.9–2.0× longer than wide; colour black.
Deep phylogenetic divergence between Scolytoplatypus and Remansus...
setae, with a patch of longer setae on each side of suture close to apex; a subapical rim runs from the suture to about interstria 8.

*Legs.* Procoxae separated by 0.5× the width of one coxa. Mesocoxae separated by 0.6× the width of one procoxa. Protibiae broad, with one distal laterally curved spine, and many additional small spines or granules on its posterior side.

*Ventral vestiture.* Metanepisternum with long bifid setae.

*Male:* unknown.

*Etymology.* Named after Sahondra Rahanitriniaina, our helpful Malagasy colleague who collected the type specimens and many other scolytine beetles during our joint field trip to Ranamafana National Park.

**Distribution and biology.** Only known from the type locality in the Ranomafana National Park. Two females were taken from a fallen branch of *Eugenia* (Myrtaceae).

*Remansus pygmaeus* Jordal, sp. n.

http://zoobank.org/5776128D-753D-4E2C-ABBB-C91FD86E7788

http://species-id.net/wiki/Remansus_pygmaeus

Figs 36–39

**Diagnosis. Female.** Posterior corners of pronotum rounded; scutellum flat at the same level as elytra; declivity characteristically truncated and marked by a circular blunt rim. One of the smallest known species in the tribe and the only species smaller than 2 mm in Africa and Madagascar. Closely related to *R. serratus*, but distinguished by the much smaller size (1.7 vs. 3.7 mm), the nearly glabrous elytral disk and posterior half of pronotum.

**Molecular data.** DNA barcodes in Table 1.

**Description. Female.** Length 1.7 mm, 1.85× longer than wide; colour black.

*Head.* Eyes separated above by 4.0× their width. Frons broadly flattened from vertex to epistoma, surface strongly reticulated, with tiny shallow punctures spaced by 1.5–2× their diameter, except smooth and impunctate on a triangular area on central lower third. Epistoma elevated, shiny, with a short median carina extending from epistoma to impunctate area. Vestiture consisting of a few scattered fine setae.

*Pronotum.* 0.8× as long as wide, sides almost straight, weakly constricted on posterior third, surface reticulate with minute shallow punctures spaced on average by 2× their diameter; median mycangial pore on anterior fifth round with a tuft of setae; pronotal vestiture consisting of sparse fine short setae, and about 20 much longer erect setae on anterior half.

*Elytra.* 1.05× longer than wide, 1.5× longer than pronotum; sides almost straight, slightly constricted just before declivity, broadly triangular at apex; striae not impressed
Deep phylogenetic divergence between *Scolytoplatypus* and *Remansus*...

except weakly so at declivital margin; strial and interstrial punctures on disk entirely confused, shallow, with minute setae of variable length. Interstriae 10 elevated to level of ventrite 1. Declivity dull, rugose, punctures variable but generally larger than on disk; vestiture on declivity of fine ground setae and fewer but coarser stiff and slightly curved short setae.

*Legs.* Procoxae separated by 0.5× the width of one coxa. Mesocoxae separated by 0.6× the width of one procoxa. Protibiae broad, with one large laterally curved distal spine, and five additional lateral small spines or granules, with small granules on the posterior face.

*Ventral vestiture.* Metanepisternum with bifid long setae.

*Male:* unknown.

*Etymology.* The Latin masculine adjective *pygmaeus* pertaining to the mythical race of African dwarfs, referring to the relative small size for this species, being the smallest species of *Scolytoplatypodini* in Africa and Madagascar.

*Distribution and biology.* Only known from the type locality in the Ranomafana National Park. One female and one pupa were taken from a fallen branch of *Weinmannia* (Cunoniaceae), about 1.5 cm in diameter. The egg tunnel was transversely spiral shaped, with eight pupation chambers directed longitudinally, like bullet chambers in a revolver barrel. Based on empty pupal chambers the brood size in this type of host is 6–10 (n=3).

Figs 40–43

Diagnosis. Male. With a unique Amasa-like truncated declivity and rounded posterior angles of the pronotum. Characters suggest a close relationship to R. pygmaeus Jordal, but it is distinguished from that species by the much larger size, narrow body shape, the pilose body, and by the slightly elevated scutellum that is not entirely flush-with the elytra. It is further distinguished from males of R. mutabilis by the dentate upper declivital margin.

Description. Male. Length 3.7 mm, 2.1× longer than wide; colour yellowish brown, darker brown on declivity and elytral lateral margins.

Head. Eyes separated above by 4.2× their width. Frons concave from vertex to epistoma via inner eye margins; upper half rugosely, densely punctured, lower half smooth and shiny. Vestiture consisting of fine setae increasing in length towards upper part of concave area, longest and most dense along upper margin from vertex to upper level of eyes.

Pronotum 0.9× as long as wide, sides subparallel, broadest on anterior half, broadly, transversely rounded in front; surface finely reticulated with minute shallow punctures irregularly spaced by 1–4× their diameter; pronotal vestiture consisting of fine short setae, slightly longer close to anterior margin.

Elytra 1.2× longer than wide, 1.7× longer than pronotum; sides almost straight, broadly triangular at apex; declivital margin marked by a dentate rim, each incision marks the end of diskal stria; striae otherwise not impressed, interstriae on disk only recognized by the lighter colour, punctures not clearly visible, confused and minute. Interstriae 10 elevated to level of ventrite I. Declivity rugosely granulated, largest granules on interstriae 1 (suture). Vestiture consisting of dense fine setae spaced on disk by less than one-third the length of each seta, on declivity about 2–3× longer than setae on disk.

Legs. Procoxae separated by 0.4× the width of one coxa. Mesocoxae separated by 0.5× the width of one procoxae. Protibiae narrow, with one larger distally lateral curved spine, and 6–7 additional lateral small spines, posterior face mainly smooth, with 4–5 tiny granules close to lateral edge.

Ventral vestiture. Metaneopisternum mainly with long simple setae, a few shorter bifid setae anteriorly.

Female: unknown.

Etymology. The Latin masculine adjective serratus means ‘serrated’, referring to the short pointed projections from interstriae at the declivital summit.

Distribution and biology. A single specimen was collected in a Malaise trap just south of Montagne d’Ambre.
Deep phylogenetic divergence between Scolytoplatypus and Remansus...

Key to the Malagasy genera and species of Scolytoplatypodini

1 Scutellum flat, broad, flush with the elytra and clearly visible; posterior edge of pronotum almost straight; female mycangium closer to anterior margin (0.22–0.28 of pronotum length); male protibiae almost parallel-sided; postero-lateral corners of pronotum without acute spine .............. Remansus Jordal, gen. n., 2

– Scutellum narrowly triangular, obliquely depressed between elytra; posterior edge of pronotum bisinuate; female mycangium closer to centre (0.33–0.36 of pronotum length); male protibiae asymmetric with large incision between lateral spines 1 and 2; postero-lateral corners of pronotum with an acute spine pointing laterad .............................................. Scolytoplatypus Schaufuss, 5

2 Declivity abrupt, marked by a circum-declivital ring, surface rough, not shining, vestiture evenly distributed in both sexes..........................................................3

– Declivity steep, gently rounded, not truncated, surface sub-shining, females with a patch of longer setae close to elytral apex.................................................4

**Phylogeny and classification**

The tree topology resulting from the Bayesian and parsimony analyses of the combined molecular data were near identical and all nodes except one received high support (Fig. 44). Scolytoplatypodini was monophyletic, with a clade consisting of the Malagasy species R. mutabilis, R. pygmaeus and R. sahondrae as the sister group to all species in Scolytoplatypus. The Asian species of Scolytoplatypus formed a sister clade to the Malagasy and African species of the genus. The three Malagasy species of Scolytoplatypus were nested in a derived monophyletic position in the Bayesian analysis, while S. rugosus was sister to the South-East African S. fasciatus in the parsimony analysis.

Parsimony analysis of the morphological data resulted in 30 most parsimonious trees. All trees revealed a strongly supported sister relationship between Remansus (including also R. serratus) and Scolytoplatypus. Some of the trees placed S. congonus as the sister to the remaining African and Asian species of Scolytoplatypus, while in two of the trees the Asian species were sister to all African species (Fig. 45). The ambiguity was likely due to S. congonus having two character states shared with Remansus, including a broad scutellum that is flush with the elytra and the nearly straight posterior margin of the pronotum (Fig. 7). However, S. congonus has spiny hind corners of the pronotum, asymmetrical male protibiae and female mycangium behind anterior third as in other Scolytoplatypus. Molecular data unambiguously resolved this issue and strongly supported the Asian-African split in Scolytoplatypus, with S. congonus as an early diverging lineage in Africa.
Figures 44–45. Phylogeny of Scolytoplatypodini. 44 Tree topology resulting from Bayesian analysis of 2902 nucleotide sites from one mitochondrial and three nuclear genes. Posterior probabilities are given above, parsimony bootstrap support below. 45 Tree topology resulting from parsimony analysis of 21 morphological characters (Table 2, Appendix).
The strongly supported split between the two basal clades justify the designation of a new genus *Remansus*. Although largely defined by plesiomorphic characters such as the ‘normal’ male protibiae (Figs 4 and 5), rounded posterior corners of pronotum, and a visible large scutellum that is flush with the elytra (Fig. 7), the new genus is also supported by a uniquely derived feature in the female mycangium being displaced anteriorly (Fig. 2 vs. Fig. 1). Taken together with the large genetic divergence in mitochondrial and nuclear loci, the new genus appears to be well supported, and hence constitutes the second genus in the tribe Scolytoplatypodini.

The molecular data also distinguished the Asian species of *Scolytoplatypus* clearly from the African species of that genus. A distinction between these two clades is supported by several morphological characters in the phylogenetic analysis as was noted in two previous publications (Beaver and Gebhardt 2006; Browne 1971). Perhaps the 28 Asian species also deserve a separate genus designation as they are clearly diagnosable. In males, the Asian species are different from the African species by having a strongly modified prosternum with nodules or hooked projections, by the longer and more triangular antennal club, and in all but two species by the large fovea on the antero-lateral angle of the male pronotum. However, this is outside the scope of this paper and more Asian taxa must be included in the molecular analyses before such changes can be made with certainty. The same applies to several African taxa where the phylogenetic data suggest taxonomic revision, including the deep divergence between the *congonus* and *kivuensis* forms of *S. congonus* (see opposing viewpoints by Browne 1971; Schedl 1975), and the near identical sequences obtained from *S. africanus* Eggers and *S. neglectus* Schedl.

In addition to four species of *Remansus*, three additional species are found in Madagascar, in the genus *Scolytoplatypus*. The new species *S. rugosus* was shown to be most closely related to the other two Malagasy species *S. hova* and *S. permirus*, although some analyses placed this species closer to *S. fasciatus* (= *S. obtectus* Schedl?), a species very similar to *S. opacicollis* Eggers. The congruence between the Bayesian analysis of the molecular data and morphology suggests that the most likely scenario is a monophyletic group of Malagasy species, as sister clade to *S. fasciatus*. The three Malagasy species of *Scolytoplatypus* share features on the female elytra by having a broad subtransverse apical flange, which, at least in comparison to the African species, seems unique. As typical *Scolytoplatypus* they share with all African species an acute spine at the postero-lateral corner of the pronotum, a bisinuate posterior margin of pronotum, a narrow scutellum that is sunken between the elytra, and similarly shaped antennal clubs in males and females. The three species therefore belong to the African group of *Scolytoplatypus*.

**The origin of Malagasy Scolytoplatypodini**

With the addition of several new taxa from Madagascar, the age estimated for the tribe Scolytoplatypodini becomes considerably older than previously reported (Jordal and Cognato 2012). Calibration of the node that includes the more advanced weevils (which here also include the molytine genus *Porthetes* and the scolytine *Scolytodes*) to
Deep phylogenetic divergence between Scolytoplatypus and Remansus...

116 Ma, a minimum age for Scolytoplatypodini, and hence the divergence of Remansus and Scolytoplatypus, was estimated to 63.1 (47–80) Ma (Table 3). Because taxon sampling in this case was somewhat biased as it was designed for a generic revision, it may have produced a slightly inflated time estimate. Hence a second analysis was made based on calibrating the node for the last common ancestor for three taxa included in a previous analysis (Jordal and Cognato 2012: S. africanus, S. eutomoides, S. tycon). This second analysis produced a minimum estimate of 42.3 (34–53) Ma for the tribe. Irrespective of these discrepancies, the age for the fungus cultivating lineage Scolytoplatypodini is moved further back in time, perhaps as far as the middle or early in the Palaeocene-Eocene period experiencing a thermal maximum (PETM, see Zachos et al. 2001). Thus, these revised estimates provide increased support for the global warming theory in explaining origins of fungus farming (Jordal and Cognato 2012).

The ancient split between Remansus in Madagascar and the Asian/African clade of Scolytoplatypus is apparently younger than the latest Gondwanan vicariance event involving Madagascar. The separation of India from Madagascar occurred at least 80 Ma (Yoder and Nowak 2006), which is almost certainly older than any of the time scenarios suggested here. Hence, the origin of both Remansus and the much later origin of Malagasy Scolytoplatypus some 13 Ma (Table 3) were likely due to overseas dispersal. While the geographical distribution of a scolytoplatypodine ancestor cannot be estimated precisely with the data presented here, it seems highly probable that the recent origin of Scolytoplatypus in Madagascar was due to dispersal from Africa to the island. The endemic species S. rugosus, S. hova and S. permirus are all deeply nested within the African clade, being closely related to the South-/South-eastern African species S. fasciatus. Due to strong wind and oceanic currents going from Madagascar to Africa, it has been postulated that post-Gondwanan colonisation of Madagascar from Africa is unlikely. However, new models for latitudinal tectonic drift have documented reversed wind and oceanic currents 15–60 Ma (Ali and Huber 2010) and thus help explaining the many origins of plant and animals during the Palaeocene to late Miocene (Samonds et al. 2012; Yoder and Nowak 2006). Even more recent colonisations from Africa have occasionally taken place in various animal groups (Miraldo et al. 2011; Vuataz et al. 2013), which indicate that reaching Madagascar have not at all been impossible during the Pliocene, albeit more difficult than in earlier times.

Acknowledgements

The author appreciates the help provided by MICET to organize our field work in Madagascar, and wish to thank the Madagascar National Park authorities for research and export permits. Also many thanks to the staff at Centre ValBio in Ranomafana NP for logistic and technical support. In addition a great thank you to the Department of Entomology at the University of Antananarivo, especially Sahondra Lalao Rahani-trinainina, for excellent field assistance. California Academy of Science provided loan of specimens, facilitated by Anthony Cognato at Michigan State University. The feedback provided by reviewers was of great help in improving the manuscript. I would also like to thank the editor for suggesting the genus name *Remansus*. This research was funded by grant 214232/F20 from the Norwegian Research Council.
